Preface

Technological developments in aerospace and other high-technology fields give rise to constantly increasing demands on part surfaces. Generally, surfaces that, e.g., withstand tribological loads, or show special properties in thermal and electrical conductivity or optical behaviour, require utilisation of coating processes.

This book presents industrially implemented coating processes in the fields of build-up welding and brazing, plasma, arc, and flame spraying, sol-gel technology as well as the thin-film technologies, chemical vapour deposition and physical vapour deposition. Particular emphasis is placed on the combination of process and materials technology in terms of producing coatings that meet all necessary requirements.

Alongside industrially relevant coating processes, newly developed technologies on the verge of industrial implementation are presented. Examples are processes for diamond synthesis, cold gas spraying or the processing of nano-sized particles.

The aim of this book is to enable engineers and technicians working in development, design, and manufacturing to be able to estimate the potential of protective surface coatings and the associated processes in their fields of activity. The intention is that coating technologies serve as an integral part of development, design, and manufacturing.

Selecting Surface-treatment Technologies

W. Tillmann, E. Vogli, Chair of Materials Technology, University of Dortmund, Germany

1.1
Introduction

Nowadays, modern production processes require inherent state-of-the-art surface technologies. Furthermore, rising standards of technical products are creating the perception that surface technologies are often the central impetus needed for meeting product specifications. Design engineers thus face two essential tasks: On the one hand, part specifications need to be transformed into properties of materials and surfaces. On the other hand, selected materials technologies have to be integrated in corresponding process chains. Apart from the required part specifications, production costs and ecological aspects are important issues.

Not only production standards but also economic conditions lead to increasing significance of surface technologies. Considering the two substantial domains of surface technology, tribology and corrosion, macroeconomics experts estimate that tribological damage causes a loss of approx. 1% of the German gross national product (GNP). The economic effect of corrosion damage is even higher, approaching approx. 3.5–4.2% of the GNP. Surface technologies therefore have to be considered as one of the key technology fields in production engineering.

Here, one possible method for selecting surface-treatment processes that satisfy existing requirements of specific parts is introduced. In addition, a variety of surface-treatment processes are compared with respect to possible fields of application and characteristics specific to the individual processes.

1.2
Requirements on Part Surfaces

Systematic selection of suitable surface treatments is always based on acquiring a complete set of requirements on the part surface with respect to intended operating conditions. According to Haefer [3], the surface is responsible for all me-
mechanical, thermal, chemical, and electrochemical interactions with the environment. This leads to the main functions that need to be fulfilled by technical surfaces:

- corrosion resistance
- wear resistance
- defined tribological behaviour
- optical behaviour
- decorative behaviour
- matched interface behaviour (e.g. for joining purposes).

In addition, especially highly specialised products may demand specific functions. Parts used in micro-technology for example can require special electromagnetic properties of surfaces.

Ultimately, requirements on part surfaces are determined by the particular load conditions under which the final product operates. Figure 1.1 illustrates the main kinds of load conditions subdivided into volume and surface loads.

Wear and corrosion are the main stresses that have to be controlled by surface technology in the realm of mechanical engineering. Incorrect materials selection as well as unsuitable or missing protective layers lead to manifold damages, some of which are shown in Figs. 1.2 and 1.3.

In many cases, appropriate surface treatment can either prevent or at least delay such damages. However, adjusting part surface characteristics carefully is essential in order to handle overall operating conditions.

Surface technology focuses on reacting adequately to the specific kinds of load and stress. For this, the materials properties of part surfaces are systematically modified or produced, particularly by means of:

![Fig. 1.1 Main volume and surface loads on parts.](image-url)
applying a protective coating to the workpiece
modifying the surface zone of the workpiece.

Typical coating processes are chemical vapour deposition (CVD), physical vapour deposition (PVD), thermal spraying, build-up brazing and welding, as well as cladding and dip coating. Surface modification processes, on the other hand,
include thermo-chemical diffusion processes, thermal surface hardening, implantation methods, and mechanical surface-hardening processes.

1.3 Selecting Coating and Surface Technologies

Designing a suitable surface treatment from a given combination of loads is challenging. Not only is it often difficult to precisely and thoroughly understand the operating conditions of a part, but very large variety of possible materials and materials technological processes have to be considered. Estimates indicate that the number of materials used in materials technology is in the range of 40 000–80 000. Moreover, including surface technologies, about 1000 different processes are used. In contrast, the mean vocabulary of a Central European spans approx. 5000 words. Quite obviously, the process of selecting an appropriate coating or surface treatment requires a systematic approach. The selection process needs to be implemented at an early stage of product development. It is necessary that developers already consider surface requirements during concept phases, directly after taking down customer and market demands. Based on the given operating conditions, four fundamental aspects should be clarified systematically [1, 6]. The following facets and questions need to be considered carefully:

1) Function:
   – What are the functional characteristics of the part surface?
   – What kind of requirements exist?

2) Purpose:
   – What needs to be maximised?
   – What needs to be minimised?

3) Limitations:
   – Which constraints and boundary conditions have to be met? e.g.
     – from a technical point of view
     – from an economic point of view
     – considering design-to-cost concepts
     – considering design for environment concepts
     – considering life-cycle costs

4) Options:
   – What options exist?

This systematic approach basically represents the general framework of the requirement catalogue concluded from the set of loads and stresses. Subsequently, individual materials and surface technologies need to be analysed and assessed against this background. This search and evaluation should be performed in an equally systematic approach. Figure 1.4 illustrates an example of a systematic analysis sheet. Here, individual coating materials and processes can be rated with respect to selected properties, prerequisites, and restrictions. The listed se-
The collection of properties within the rating matrix as well as the corresponding prerequisites and restrictions originate from the formerly compiled catalogue of requirements.

The approach presented here describes a workable method of correlating a catalogue of requirements with appropriate surface technologies. Certainly, the quality of results is determined and limited by the requirement catalogue developed in phase one. Furthermore, this methodology requires comprehensive knowledge of available materials and processes, a frequently limiting factor due to the already mentioned manifold process varieties and materials.

### 1.4 Processes for Surface Modification and Coating

Giving a detailed overview of the different surface modification and coating processes would go far beyond the scope of this chapter. Therefore, a general summary of the most important process classes is presented, along with their individual properties and requirements.

#### Table 1.1: Rating Matrix Example

individual assets and drawbacks. Figure 1.5 shows the systematic classification of surface-modification processes.

Selected process technologies are presented in Table 1.1, including basic advantages and disadvantages [5].

Unlike surface-modification processes, coating involves covering the surface of a workpiece with a well-bonded layer of shapeless material. A possible classification of coating technologies is given in Fig. 1.6.

Bond strength to the substrate material primarily determines the quality of a coating. This macroscopic property is controlled by:
- materials combination
- type of interface zone
- microstructure and process conditions
- substrate type and pre-treatment.

A strong atomic bond in the contact zone is most favourable, provided that internal stresses within the coating are not too high and no long-term degradation occurs within the coating/substrate composite. Coating process and material combinations determine whether mechanical, chemical, or electrostatic bonds prevail, or whether diffusion occurs. Thus, preparation of the workpiece is a

</tbody>
</table>
crucial factor in obtaining good coating adhesion. Apart from removing contamination, pre-treatments activate the substrate surface and therefore substantially influence the bond between coating and substrate. Typical mechanisms of surface activating are:

- creating defects in the substrate
- increasing surface energy
- removing oxide layers.

Table 1.2 summarises different coating technologies in common use and includes important process characteristics [4, 6].
